

Highlights

An Exact Decomposition of Paired Score Differences: Separating Prior Fit from Within-Group Resolution

- Exact identity splits a paired score gain into prior fit and within-group resolution
- The remainder is the classical resolution term, for a model pair rather than one
- Cluster-robust inference, a CLT, and reduction to a clustered Diebold-Mariano test
- Leave-one-out relabelling removes an exact $(n_c - 1)/n_c$ plug-in attenuation bias
- A released debiasing method's ten-point metric gain is almost all prior fit
